Abstract. An oracle A is k-cheatable if there is a polynomial-time algorithm to determine the answers to 2^k parallel queries to A from the answers to only k queries to some other oracle B. It is known that 1-cheatable sets cannot be bi-immune for P. In contrast, we construct 2-cheatable sets that are bi-immune for arbitrary time complexity classes. In addition, for each k, we construct a set that is $(k+1)$-cheatable, but not k-cheatable; we show that this separation does not hold with bi-immunity. We show that if a recursive set A is bi-immune for P then there exists a nontrivial 1-cheatable set that is polynomial-time m-reducible to A. Consequently if NP contains a set that is bi-immune for P then NP contains a set that is not polynomial-time Turing-equivalent to a self-reducible set.

1. Introduction

Complexity theory deals with how hard problems are. Time, space, and alternation have served as measures of difficulty. Recently, researchers have looked at the number of queries that must be made to an oracle by a polynomial-time algorithm that solves a problem, as a measure of that problem's difficulty [13, 22]. When we consider number-of-queries as a complexity measure, it is natural to consider the "complexity classes" of functions and sets induced by that measure. We call these complexity classes *bounded query classes*, because they contain sets and functions computable by algorithms that make a bounded number of queries to an oracle. Since number-of-queries is not a complexity measure in the sense of Blum, many expected results about complexity measures do not apply to bounded query classes. Several papers [1, 2, 3, 5, 7] investigate the relationships among different bounded query classes. One basic question is "When do k queries to an oracle enable us to compute more functions in polynomial time than only $k-1$ queries?"

The basic question in the preceding paragraph has at least sixteen interpretations. Queries may be made in series as in a Turing reduction (serial queries have also been called "adaptive" [12] because each query is allowed to depend on the answers

* Current address: Department of Computer Science, P.O. Box 2158, Yale Station, New Haven, CT 06520, U.S.A. Research supported by a Fannie and John Hertz Foundation fellowship and by NSF Grant CCR-8808949. Part of this work was done while the author was a graduate student at Stanford University.

to the previous queries), or in parallel as in a truth-table reduction. It may be required that the $k-1$ queries be made to the same oracle as the k queries, or it may be permitted that the $k-1$ queries be made to a different oracle. The set of $k-1$ query strings may be required to be a subset of the set of k query strings, or the set of $k-1$ query strings may be allowed to be any $(k-1)$-element subset of Σ^*.

A set A is defined to be *k-query p-terse* if k parallel queries to A allow us to compute more functions than only $k-1$ serial queries to A. A set A is defined to be *k-query p-superterse* if k parallel queries to A allow us to compute more functions than only $k-1$ serial queries to B for every set B. The reason for defining p-superterseness is that most proofs of p-terseness are in fact proofs of p-superterseness [2, 4, 5, 7]; in addition k-query p-superterseness is the strongest of our sixteen ways of stating that k queries to an oracle enable us to compute more functions in polynomial time than only $k-1$ queries. A special case is 2-query p-terseness; it is known that a set A is 2-query p-terse if and only if A is 2-query p-superterse [4].

A set A is defined to be *k-cheatable* if there exists a set B such that 2^k parallel queries to A *do not* allow us to compute more functions than only k serial queries to B. For large k, k-cheatability can be seen as a dramatic failure to be $(k+1)$-query p-superterse. In the special case $k=1$, this failure is not so dramatic: a set A is 1-cheatable if and only if A is not 2-query p-superterse. Efforts to extend a number of results about 2-query p-superterseness to general results about k-query p-superterseness have been unsuccessful [2, 4, 5]. However, some of those results can be extended to general results about k-cheatability. We think that results about 2-query p-superterseness are best understood as results about cheatability, not as results about p-superterseness.

A set A is *p-superterse* (*p-terse*) if A is k-query p-superterse (p-terse) for every k. A set A is *cheatable* if A is k-cheatable for some k. A number of papers study the properties of non-p-superterse sets [1, 2, 4, 5, 7]. The class of cheatable sets is a proper subset of the class of non-p-superterse sets. While we do not claim that the class of cheatable sets is more interesting than the general class of non-p-superterse sets, there are a number of interesting results about cheatable sets that do not hold for all non-p-superterse sets or else admit only weaker analogies for general non-p-superterse sets. For example, all cheatable sets are recursive [11]; however non-p-superterse sets can be nonrecursive [8, 9]. Cheatability is preserved by polynomial-time Turing reductions [1]; non-p-superterseness is not [1]. A cheatable set cannot be self-reducible unless it is in P [1, 17]; no corresponding result is known for non-p-superterse sets. All cheatable sets are computable in polynomial time with polynomial advice [1], whereas non-p-superterse sets are only known to be computable in exponential time with polynomial advice [1]. It is known that n parallel queries to a cheatable set can be answered by making only a constant number of queries to some oracle B for all n [4]; a corresponding result says that n parallel queries to a non-p-superterse set A can be answered by making $O(\log n)$ queries to some oracle B [7]. (This allows us to classify every set A based on the asymptotic number of queries to a second oracle required in order to answer n

parallel queries to A: 0 queries iff A is polynomial-time computable; $\Theta(1)$ queries iff A is cheatable but not polynomial-time computable; $\Theta(\log n)$ queries iff A is non-p-superterse but not cheatable, n queries iff A is p-superterse.) A cheatable set cannot be NP-hard under polynomial-time Turing reductions unless P = NP [4]; the best known corresponding result says that a non-p-superterse set cannot be NP-hard under polynomial-time truth-table reductions unless P = UP [5].

Some results hold both for cheatable sets and for non-p-superterse sets. Because cheatable sets can have arbitrarily high time complexity [2], no recursive set can be hard for the class of cheatable sets under polynomial-time Turing reductions. Therefore the class of cheatable sets does not contain a polynomial-time Turing complete set, and the class of recursive non-p-superterse sets does not contain a polynomial-time Turing complete set. Since every truth-table degree (no time bound) contains a non-p-superterse set [8], no set can be hard for the class of non-p-superterse sets under polynomial time Turing reductions. Therefore the class of non-p-superterse sets does not contain a polynomial-time Turing complete set.

The relationship of cheatability to completeness, self-reducibility, and NP-hardness has already been established. In this paper we investigate the relationship of cheatability to bi-immunity for P. This question was motivated by the recursion-theoretic Nonspeedup Theorem [8], which states that all "recursively" cheatable sets are recursive; by analogy the Non-speedup Theorem suggests that cheatable sets might be easy in some standard complexity-theoretic sense. Amir and Gasarch [2] and (later) ourselves [6] have shown that 1-cheatable sets cannot be bi-immune for P, so membership in a 1-cheatable set can be decided in polynomial time infinitely often. In contrast, we show that 2-cheatable sets can be bi-immune for P. This is a qualitative distinction between 1-cheatable sets and the general class of cheatable sets, which was unexpected because the class of "recursively" 1-cheatable sets is equal to the class of "recursively" cheatable sets (both are equal to the class of recursive sets). We construct sets that are $(k+1)$-cheatable but not k-cheatable for each k. We show that if a recursive set L is bi-immune for P then L contains a 1-cheatable subset that is not in P but is polynomial-time m-reducible to L. This result has interesting consequences: it shows that the separation of $(k+1)$-cheatable from k-cheatable does not hold with bi-immunity, and it provides a plausible condition under which NP intersects a non-self-reducible polynomial-time Turing degree (partially answering a question of Selman [26]).

2. Bounded query reductions

We say that n queries to an oracle are made *in parallel* if a list of all n queries is formed before any of them is made. Otherwise we say that n queries are made *in series*, or simply that n queries are made. The difference is that computation is allowed between serial queries to an oracle—the answer to a prior query may determine what query is to be made next.

Definition 2.1. A set A is *polynomial-time k-Turing reducible* to B ($A \leq^{\mathrm{P}}_{k\text{-T}} B$) if there is a polynomial-time algorithm relative to B that determines whether x is in A by making only k queries to B.

A set A is *polynomial-time k-truth-table reducible* to B ($A \leq^{\mathrm{P}}_{k\text{-tt}} B$) if there is a polynomial-time algorithm relative to B that determines whether x is in A by making only k parallel queries to B.

The definitions above are equivalent to definitions made in [12] and [23]. Note that our definitions of polynomial-time k-Turing reducibility and polynomial time k-truth-table reducibility make sense if A or B or both are replaced by polynomial length-bounded functions, instead of oracles.

The function F^A_k defined below is a convenient notation for the results of k parallel queries to A.

Definition 2.2. $\mathrm{F}^A_k(x_1, \ldots, x_k) = \langle \chi_A(x_1), \ldots, \chi_A(x_k) \rangle$, where χ_A is the characteristic function of A.

The function F^A_k is important because it is 1-Turing complete for the class of functions that are polynomial-time k-truth-table reducible to A. In fact, $f \leq^{\mathrm{P}}_{k\text{-tt}} A$ if and only if $f \leq^{\mathrm{P}}_{1\text{-T}} \mathrm{F}^A_k$.

Definition 2.3.

- A set A is *k-query p-terse* if $\mathrm{F}^A_k \not\leq^{\mathrm{P}}_{(k-1)\text{-T}} A$.
- A set A is *p-terse* if A is k-query p-terse for all k.
- A set A is *k-query p-superterse* if $(\forall B)[\mathrm{F}^A_k \not\leq^{\mathrm{P}}_{(k-1)\text{-T}} B]$.
- A set A is *p-superterse* if A is k-query p-superterse for all k.
- A set A is *k-cheatable* if $(\exists B)[\mathrm{F}^A_2 \leq^{\mathrm{P}}_{k\text{-T}} B]$.
- A set A is *cheatable* if A is k-cheatable for some k.

Although we defined two different brands of k-query p-terseness (super and regular), we do not define both analogous brands of k-cheatability because they lead to equivalent definitions of cheatability.

We will need the following obvious result, which is proved in [6].

Theorem 2.4. *If* $\mathrm{F}^A_{(k+1)} \leq^{\mathrm{P}}_{k\text{-tt}} A$ *then*

(i) $(\forall n)[\mathrm{F}^A_n \leq^{\mathrm{P}}_{k\text{-tt}} A]$.

(ii) *A is k-cheatable.*

See [8, 9] for some results on bounded-query reductions in recursion theory.

3. An oracle-free definition of cheatability

The concepts of k-query p-superterseness and k-cheatability can be described in a purely combinatorial fashion without recourse to oracles. In order to do so we

present the concept of computability by a set of k polynomial-time computable functions. (The results from this section will be useful in Section 6.)

Definition 3.1. The total function h is *computable by a set of k polynomial-time computable functions* if there exist k polynomial-time computable functions $g_1, \ldots, g_k$ such that

$$(\forall x)[h(x) \in \{g_i(x) \mid 1 \leq i \leq k\}].$$

Equivalently, the function h is computable by a set of k polynomial-time computable functions if, for each x, we can compute in polynomial time a length-k list that includes $h(x)$. When h is computable by a set of k polynomial-time computable functions, we say informally that *there are only k possible values for $h(x)$*.

The following theorem [7] provides an equivalence between bounded-query reducibility to an oracle and computability by a set of polynomial-time computable functions.

Theorem 3.2. (i) *If* $(\exists B)[h \leq^{\mathrm{P}}_{k\text{-T}} B]$ *then h is computable by a set of 2^k polynomial-time computable functions.*

(ii) *If h is computable by a set of 2^k polynomial-time computable functions then* $(\exists B)[h \leq^{\mathrm{P}}_{k\text{-tt}} B]$.

This theorem immediately provides the following necessary and sufficient conditions for p-superterseness and cheatability.

Theorem 3.3

- *A is k-query p-superterse iff F^A_k is not computable by a set of 2^{k-1} polynomial-time computable functions.*
- *A is p-superterse iff F^A_k is not computable by a set of 2^{k-1} polynomial-time computable functions for any value of k.*
- *A is k-cheatable iff $\mathrm{F}^A_{2^k}$ is computable by a set of 2^k polynomial-time computable functions.*
- *A is cheatable iff $\mathrm{F}^A_{2^k}$ is computable by a set of 2^k polynomial-time computable functions for some k.*

In [4] we prove the following.

Theorem 3.4. *If* $\mathrm{F}^A_{2^k} \leq^{\mathrm{P}}_{k\text{-T}} B$ *then*

(i) *for every $n \geq 2^k$, any n parallel queries to A can be answered by a polynomial time algorithm that asks only $2^k - 1$ of the same queries in parallel.*

(ii) $(\forall n)[\mathrm{F}^A_n \leq^{\mathrm{P}}_{k\text{-T}} B]$.

The name cheatable is motivated by part (i) of this theorem, which states that if A is cheatable then any n queries to A can be answered by a polynomial-time algorithm that asks only a fixed number (independent of n) of the same questions. If the answers to a true-false test are given by a cheatable set, then a student up to no good would only need to copy a fixed number of answers in order to determine them all. The theorem provides the following necessary and sufficient conditions for cheatability.

Theorem 3.5. *A set A is cheatable if and only if there exists a constant k such that for all n, F_n^A is computable by a set of k polynomial-time computable functions.*

4. Are cheatable sets easy infinitely often?

If F_2^A can be computed by asking k queries to some other oracle within unbounded computation time (i.e., $(\exists B)[F_2^A \leq_{k\text{-}T} B]$), then we might say that A is recursively cheatable. However, in [8] we prove the Nonspeedup Theorem, which states that A is "recursively cheatable" in this sense if and only if A is recursive. By analogy, we might conjecture that all cheatable sets are in P. However, Amir and Gasarch [2] have constructed 1-cheatable sets A of arbitrarily great time complexity. Therefore we seek to prove that cheatable sets are easy in some sense that is weaker than polynomial-time computability. In [1], it is proved that all cheatable sets have small circuits. In this section we investigate whether cheatable sets must be easy infinitely often, i.e., whether they cannot be bi-immune for P.

In [3], Balcazar and Schöning formalized the notion of being easy infinitely often, which was previously considered in [11] and [24].

Definition 4.1.

- A set A is *immune* for a class $\mathscr{C}$ if A contains no infinite subset that belongs to $\mathscr{C}$.
- A set A is *co-immune* for a class $\mathscr{C}$ if $\bar{A}$ is immune for $\mathscr{C}$.
- A set A is *bi-immune* for a class $\mathscr{C}$ if A is immune for $\mathscr{C}$ and co-immune for $\mathscr{C}$.

The authors of [3, 11, 24] have noted that a set A is easy infinitely often if and only if A is not bi-immune for P. Amir and Gasarch [2] have found an elegant proof that no 1-cheatable set is bi-immune for P; a constructive proof of that fact can be found in [6]. In contrast to the theorem that no 1-cheatable set can be bi-immune for P, we construct a 2-cheatable set that is bi-immune for P.

Lemma 4.2. *There exists a set A over the alphabet $\{0\}$ such that A is bi-immune for P and such that any three parallel queries to A can be answered in polynomial time by making only two of the same queries in parallel.*

Proof. Define $\text{tow}(0) = 1$ and $\text{tow}(i+1) = 2^{\text{tow}(i)}$. Define $\log^{(0)} x = x$ and $\log^{(i+1)} x = \log \log^{(i)} x$. Define $\log^* x$ to be the greatest i such that $\log^{(i)} x \geq 1$.

By the extended time hierarchy theorem [15], there is a set B in DTIME(17^{2^n}) that is bi-immune for DTIME(3^{2^n}). Let

$$A = \{0^x \mid 0^{\text{tow}(\log^* x)} \in B\}.$$

Then A is produced by dividing 0^* into blocks such that the block beginning with i contains $2^i - i$ elements; every element of a block belongs to A if and only if the first element of that block belongs to B.

As in the construction of a hard 1-cheatable set [2], we can answer three parallel queries to A by asking only two of them. This is proved as follows: If two of the queries belong to the same block, then we ask one of the queries in each block, and the answer to the remaining query is implied. Otherwise the queries belong to three distinct blocks. Assume that the shortest query belongs to the block that starts with 0^z. The length of the longest query must be at least 2^{2^z}. We can directly compute the answer to the smallest query in time $17^{2^z} = (2^{2^z})^{17/2}$, which is a polynomial in the input length. We ask the oracle the answers to the two larger queries.

If A has an infinite $O(n^k)$ time subset S, then we let

$$T = \{0^{\text{tow}(\log^* x)} \mid 0^x \in S\}.$$

Therefore T is an infinite subset of B. We can determine whether $0^y \in T$ by checking at most $2^y - y$ candidates for x in the definition of T; the length of each candidate is at most 2^y. Thus we can test whether $y \in T$ in time $(2^y - y)(2^y)^k \leq 2^{(k+1)y} = O(3^{2^y})$. Thus $T \in$ DTIME(3^{2^n}), which contradicts the immunity of B. We obtain a similar contradiction if $\bar{A}$ has an infinite $O(n^k)$ time subset. Thus A is bi-immune for P. □

By Theorem 2.4(ii), it follows that there exists a set A over the alphabet $\{0\}$ that is 2-cheatable and bi-immune for P. The existence of a 2-cheatable set A over an arbitrary alphabet such that A is bi-immune for P will follow from the next lemma. (The proof is a straightforward, but notationally cumbersome, modification of the preceding proof.)

Lemma 4.3. *Let h be a total recursive function, and let Σ be an alphabet. Then there exists a set A over the alphabet Σ such that A is bi-immune for* DTIME($h(n)$), *and such that any three parallel queries to A can be answered by making only two of the same queries in parallel.*

Proof. Let g be a strictly increasing, time-constructible function that is at least $|\Sigma|^n h(n)$. We will begin by constructing a set A over the alphabet $\{0\}$ such that A is 2-cheatable and bi-immune for DTIME($g(n)$). Define $g^{(0)}(n) = n$ and $g^{(i+1)}(n) = g(g^{(i)}(n))$. Define $g^{(-*)}(n)$ to be the greatest i such that $g^{(i)}(1) \leq n$.

By the extended time hierarchy theorem [18], let B be a set in DTIME($(g(g(n)))^4$) that is bi-immune for DTIME($(g(g(n)))^2$). Let

$$A = \{0^x \mid 0^{g^{(g^{(-*)}(x))}(1)} \in B\}.$$

Then A is produced by dividing 0^* into blocks such that the block beginning with 0^i contains $g(i)-i$ elements; every element of a block belongs to A if and only if the first element of that block belongs to B.

As in [2], we can answer three parallel queries to A in polynomial time by asking only two of them. This is proved as follows: if two of the queries belong to the same block, then we ask one of the queries in each block, and the answer to the remaining query is implied. Otherwise the queries belong to three distinct blocks. Assume that the shortest query belongs to the block that starts with 0^z. The length of the longest query must be at least $g(g(z))$. We can directly compute the answer to the smallest query in time $(g(g(z)))^4$, which is a polynomial in the input length. We ask the oracle the answers to the two larger queries.

If A has an infinite subset $S \in \mathrm{DTIME}(g(n))$, then we let

$$T = \{0^{g^{(g(\cdots g(x)\cdots)(1)}} \mid 0^x \in S\}.$$

Therefore T is an infinite subset of B. We can determine whether $0^y \in T$ by checking at most $g(y)-y$ candidates for x in the definition of T; the length of each candidate is at most $g(y)$. Thus we can test whether $y \in T$ in time $(g(y)-y)g(g(y)) \leq (g(g(y)))^2$. Thus $T \in \mathrm{DTIME}((g(g(y)))^2)$, which contradicts the immunity of B. We obtain a similar contradiction if $\bar{A}$ has an infinite subset in $\mathrm{DTIME}(g(n))$. Thus A is bi-immune for $\mathrm{DTIME}(g(n))$.

So far we have constructed a set A over the alphabet $\{0\}$ such that A is bi-immune for $\mathrm{DTIME}(g(n))$, and such that any three parallel queries to A can be answered by making only two of the same queries in parallel. In order to extend this result to an arbitrary alphabet Σ, let $A' = \{s \mid 0^{|s|} \in A\}$. Obviously, any three parallel queries to A' can be answered by making only two of the same queries in parallel. If A' has an infinite $\mathrm{DTIME}(f(n))$ subset then a straightforward argument shows that A has an infinite $\mathrm{DTIME}(|\Sigma|^n f(n))$ subset. Thus A' is immune for $\mathrm{DTIME}(g(n)/|\Sigma|^n)$, which is equal to $\mathrm{DTIME}(h(n))$. Similarly, A' is co-immune for $\mathrm{DTIME}(h(n))$, so A' is bi-immune for $\mathrm{DTIME}(h(n))$. □

Theorem 4.4. *Let h be a total recursive function, and let Σ be an alphabet. Then there exists a 2-cheatable set A over the alphabet Σ such that A is bi-immune for* $\mathrm{DTIME}(h(n))$.

Proof. This follows from Lemma 4.3 and Theorem 2.4(ii). □

The extended time hierarchy theorem is a very powerful tool. It is interesting to note that we did not really need to use it in order to prove the preceding results, because the techniques in [11] and [3] can be easily extended to show that if $p(n)$ is time constructible and $p(n) \geq 2^n q(n) \log(q(n))$ then there is a set B in $\mathrm{DTIME}(p(n))$ that is bi-immune for $\mathrm{DTIME}(q(n))$. By letting $p(n) = (g(g(n)))^4$ and $q(n) = (g(g(n)))^2$, it follows that if $g(n) \geq 2^n$ then there is a set in $\mathrm{DTIME}((g(g(n)))^4)$ that is bi-immune for $\mathrm{DTIME}((g(g(n)))^2)$. This enables the

proof above to go through without the extended time hierarchy theorem, whenever $g(n) \geq 2^n$. The theorem follows for smaller functions, because if a language is bi-immune for DTIME(2^n) then it must be bi-immune for all subsets of DTIME(2^n). Recently, Goldsmith et al. [16] have independently discovered another proof of our result.

The next corollary implies the existence of 2-cheatable sets that are not 1-cheatable.

Corollary 4.5. *There exists a set A such that*

$$(\forall n \geq 2)[\mathrm{F}_n^A \leq_{2\text{-tt}}^{\mathrm{P}} A \text{ but } (\forall B)[\mathrm{F}_n^A \not\leq_{1\text{-tt}}^{\mathrm{P}} B]].$$

Proof. Choose a recursive function h that dominates all polynomials, and let A be as in Lemma 4.3. The set A is constructed so that $\mathrm{F}_3^A \leq_{2\text{-tt}}^{\mathrm{P}} A$. By Theorem 2.4(i)

$$(\forall n)[\mathrm{F}_n^A \leq_{2\text{-tt}}^{\mathrm{P}} A].$$

Since A is bi-immune for P, A cannot be 1-cheatable so

$$(\forall n \geq 2)(\forall B)[\mathrm{F}_n^A \not\leq_{1\text{-tt}}^{\mathrm{P}} B]. \qquad \square$$

5. Recursive bi-immune sets have hard 1-cheatable subsets

In the preceding section we saw that 1-cheatable sets cannot be bi-immune for P. In this section we show that if A is recursive then $\bar{A}$ has an infinite polynomial-time computable subset or A has an infinite 1-cheatable subset. Thus a recursive set cannot be co-immune for P and immune for 1-cheatable. Consequently if a recursive set is bi-immune for P then it contains a 1-cheatable subset that is not in P.

Lemma 5.1. *Let A be a recursive set.*

(i) *There is an infinite set $S \in \mathrm{P}$ such that $S \cap A$ is an infinite 1-cheatable set or $S \cap \bar{A}$ is an infinite polynomial-time computable set.*

(ii) *There exist sets B and B' such that*

- *$B \subseteq A$ and $B' \subseteq \bar{A}$,*
- *B and B' are 1-cheatable,*
- *$B \leq_{\mathrm{m}}^{\mathrm{P}} A$,*
- *B is infinite or B' is infinite.*

(iii) *A or $\bar{A}$ contains an infinite 1-cheatable subset.*

Proof. (i) Let M be a Turing machine that accepts A. Let $f(n)$ be the running time of M on input 0^n. Let $T(n)$ be a fully time-constructible function that is at least $\max(2^n, f(n))$. (For example, we could let $T(n)$ be the running time of a Turing machine M_T which, on input of length n, computes $\max(2^n, f(n))$ in unary.) Let $T^{(k)}$ be the composition of T with itself k times. Let

$$S = \{0^{T^{(k)}(1)} \mid k \geq 0\}.$$

Then S is infinite. It is obvious that S is polynomial-time computable. We show that $S \cap A$ is 1-cheatable. Given strings x and y, we can determine in polynomial time whether x and y are in S. If $x \notin S$, then we make one query to $S \cap A$ to determine if $y \in S \cap A$, and we know that $x \notin S \cap A$. Similarly if $y \notin S$. If $x \in S$ and $y \in S$, then $x = y$ or $|x| \geq T(|y|)$ or $|y| \geq T(|x|)$. In the first case, only one query to $S \cap A$ is needed. In the second and third cases, we query $S \cap A$ about the larger query, and we run M on the smaller query, using time that is linear in the length of the input. Thus $S \cap A$ is 1-cheatable. Similarly $S \cap \bar{A}$ is 1-cheatable. If $S \cap A$ is infinite then $S \cap A$ is an infinite 1 cheatable subset of A. If $S \cap A$ is finite, then $S \cap \bar{A}$ differs from S on only finitely many strings, so $S \cap \bar{A}$ is an infinite polynomial-time computable subset of $\bar{A}$.

(ii) Let $B = S \cap A$ and let $B' = S \cap \bar{A}$.

(iii) B and B' are 1-cheatable subsets of A. B or B' is infinite. □

Consequently we obtain Amir and Gasarch's [2] result.

Corollary 5.2. *For any total recursive function T, there exists a 1-cheatable set that is not in* DTIME($T(n)$).

Proof. By the extended time hierarchy theorem [15], there exists a recursive set A that is bi-immune for DTIME($T(n)$). By Lemma 5.1(iii), we can let B be an infinite 1-cheatable subset of A or $\bar{A}$. The bi-immunity of A guarantees that B is not in DTIME($T(n)$). □

Lemma 5.3. *Let A be a recursive set that is bi-immune for* P.

(i) *There exists a set $S \in$ P such that $S \cap A$ is 1-cheatable, but not in* P.

(ii) *There exists a set B such that*

- $B \subseteq A$,
- *B is 1-cheatable*,
- $B \leq_m^P A$,
- $B \notin$ P.

Proof. Let A be a recursive set that is bi-immune for P.

(i) By Lemma 5.1(i), there is an infinite set $S \in$ P such that $S \cap A$ is an infinite 1-cheatable set or $S \cap \bar{A}$ is an infinite polynomial-time computable set. Because A is co-immune for P, the second possibility is ruled out, so $S \cap A$ is an infinite 1-cheatable set. Because A is immune for P, the set $S \cap A$ cannot be in P.

(ii) Let $B = S \cap A$. □

In [25], Schnorr defined self-reducibility.

Definition 5.4. A set A is self-reducible if there is a polynomial-time bounded oracle Turing machine M such that

- all strings queried by M are strictly shorter than the input string,
- the language accepted by M^A (machine M computing with oracle A) is A.

Since SAT (the set of satisfiable Boolean formulas) is self-reducible, every NP-complete set is polynomial-time m-equivalent to a self-reducible set. A natural question is whether every set in NP is polynomial-time Turing equivalent to a self-reducible set. (In [26], Selman posed that question for d-self-reducibility, which is a special case of self-reducibility.)

Theorem 5.5. *If A is a recursive set that is bi-immune for* P *then there exists a set B such that*

(i) $B \notin \mathrm{P}$,

(ii) $B \leq_m^{\mathrm{P}} A$,

(iii) $A \not\leq_T^{\mathrm{P}} B$,

(iv) *if S is self-reducible and $S \leq_T^{\mathrm{P}} B$ then* $S \in \mathrm{P}$,

(v) *if S is self-reducible then $B \not\leq_T^{\mathrm{P}} S$.*

Proof. (i), (ii) Let A be a recursive set that is bi-immune for P. By Lemma 5.3(ii), there exists a set B such that B is 1-cheatable, $B \leq_m^{\mathrm{P}} A$ and $B \notin \mathrm{P}$.

(iii) Let S be any set such that $S \leq_T^{\mathrm{P}} B$. Then S is 1-cheatable [1]. However if S is 1-cheatable then S is not bi-immune for P. Therefore $S \neq A$.

(iv) If S is self-reducible and 1-cheatable then $S \in \mathrm{P}$ [1].

(v) If $S \in \mathrm{P}$ and $B \notin \mathrm{P}$ then $B \not\leq_T^{\mathrm{P}} S$. □

This theorem enables us to show that if NP contains a language that is bi-immune for P then there is a non-self-reducible NP p-degree.

Theorem 5.6. *If* NP *contains a set that is bi-immune for* P *then*

(i) NP − P *contains a 1-cheatable set.*

(ii) NP − P *contains a set B such that every self-reducible set that is polynomial-time Turing-reducible to B is in* P.

(iii) NP − P *contains a set B that is not polynomial-time Turing-equivalent to any self-reducible set.*

Proof. Let A be a set in NP that is bi-immune for P.

(i) By Lemma 5.3(ii), there exists a set B such that $B \leq_m^{\mathrm{P}} A$, $B \notin \mathrm{P}$ and B is 1-cheatable. The first two conditions imply that $B \in \mathrm{NP} - \mathrm{P}$.

(ii) By Theorem 5.5(i), (ii), (iv) there exists a set B such that $B \leq_m^{\mathrm{P}} A$, $B \notin \mathrm{P}$, and every self-reducible set that is polynomial-time Turing-reducible to B is in P.

(iii) By Theorem 5.5(i), (ii), (v) there exists a set B such that $B \leq_m^{\mathrm{P}} A$, $B \notin \mathrm{P}$, and B is not polynomial-time Turing-equivalent to any self-reducible set. □

Since Bennett and Gill [10] have shown that NP contains a language that is bi-immune for P under almost all relativizations, our assumption that NP contains a language that is bi-immune for P is plausible. (Since Homer and Maass [19] have constructed a relativized world in which $\mathrm{P} \neq \mathrm{NP}$ but no language in NP is bi-immune

for P, we do not expect a proof of our assumption to be forthcoming.) We think that the conclusions in this theorem are suggestive of the likely behavior of sets in NP. Parts (ii) and (iii) of this theorem partially answer Selman's question in [26]; Ko [21] has also made some progress on Selman's question.

By closely examining the proof of the preceding theorem, we can obtain a slightly stronger, but more complicated result. Let A be a set in NP that is bi-immune for P. Then $A \in \mathrm{DTIME}(2^n)$. As in the proof of Lemma 5.1(i), we define a set $S = \{0^{\mathrm{tow}(n)} \mid n \geq 0\}$. Either $S \cap A$ is an infinite 1-cheatable subset of A, or $S \cap \bar{A}$ is an infinite polynomial-time computable subset of $\bar{A}$. Since A is bi-immune for P, we conclude that $B = S \cap A$ is an infinite 1-cheatable set in NP. However, instead of assuming that NP contains a language that is bi-immune for P, it would have been sufficient to assume directly that the set $S = \{0^{\mathrm{tow}(n)} \mid n \geq 0\}$ contains a subset B that is in NP$-$P. As in [18], this is easily seen to be equivalent to assuming that there is a tally set in $\bigcup_{k>0} \mathrm{NTIME}((\mathrm{tow}(n))^k) - \bigcup_{k>0} \mathrm{DTIME}((\mathrm{tow}(n))^k)$. (Consider $\{0^n \mid 0^{\mathrm{tow}(n)} \in S\}$.) That is equivalent to assuming that $\bigcup_{k>0} \mathrm{NTIME}(2^{(\mathrm{tow}(n))^k}) \neq \bigcup_{k>0} \mathrm{DTIME}(2^{(\mathrm{tow}(n))^k})$. Some results like this were obtained independently in [17].

6. A hierarchy of cheatable sets

By Corollary 4.5, there exists a 2-cheatable set that is not 1-cheatable. The following theorem uses diagonalization to extend this result.

Theorem 6.1. *If $k \geq 1$ then there exists a k-cheatable set that is k-query p-superterse.*

Proof. We construct a set A such that A is k-cheatable, but F_k^A is not computed by a set of $(2^k - 1)$ polynomial-time computable functions. The second condition implies that A is k-query p-superterse, by Theorem 3.3(i). Let M_i be the ith Turing machine that computes a set of $(2^k - 1)$ polynomial-time computable functions[1] (in a canonical enumeration of such machines). Let $w_{j,n} = 0^j 1^{n-j}$.

Stage 0: $n := k$; $A := \emptyset$.

Stage $i > 0$: $n := 2^n$;

for all strings s whose length is less than n do

1: if $\chi_A(s)$ has not yet been defined then $\chi_A(s) := 0$;

simulate M_i for 2^n steps on input $(w_{1,n}, w_{2,n}, \ldots, w_{k,n})$;

2: define $\mathrm{F}_k^A(w_{1,n}, w_{2,n}, \ldots, w_{k,n})$ so as to make all of M_i's answers wrong.

[1] The particular machine model is not important here. For concreteness we can assume that the TM has $2^k - 1$ different output tapes on which to print the values of the $2^k - 1$ polynomial-time computable functions. Since k is a constant, the TM can easily be made to run in polynomial time, by evaluating one polynomial-time computable function at a time.

For each i there are infinitely many Turing machines whose behavior is identical to that of M_i (by standard padding techniques). Since 2^n dominates every polynomial, the simulation in the construction above allows some machine that is equivalent to M_i to run to completion. The construction defeats that machine, and hence defeats M_i. Therefore F_k^A is not computed by any set of (2^k-1) polynomial-time computable functions.

We say that the string s is used in the diagonalization if $\chi_A(s)$ is defined at line 2, rather than at line 1. The string $s = w_{j,n}$ is used in the diagonalization if and only if n is a tower of 2s and j is between 1 and k. Thus we may determine in polynomial time whether s is used in the diagonalization.

To show that A is k-cheatable it suffices to show that $F_{k+1}^A \leq_{k\text{-tt}}^P A$ (by Theorem 2.4(ii)). If one of the $k+1$ input strings s is not used in the diagonalization then $s \notin A$, so we use our k parallel queries to determine the membership of the other k strings.

If all $k+1$ input strings are used in the diagonalization then one of their lengths is logarithmic in the length of the longest string. Let s be such a string. We determine whether $s \in A$ by running the construction at stage $\log^*(|s|)$. The simulation of M_i dominates the running time of the stage. The simulation can be performed in $O(4^{|s|})$ steps [20]. This time is linear in the length of the input. We use our k parallel queries to determine the membership of the other k strings. □

We immediately obtain the following.

Corollary 6.2. *Let $k \geq 1$. Then*

(i) *there exists a set that is k-cheatable but not $(k-1)$-cheatable,*

(ii) *there exists a set that is k-query p-superterse but not $(k+1)$-query p-terse,*

(iii) *there exists a set A such that*

$$(\forall n \geq k)[F_n^A \leq_{k\text{-tt}}^P A \text{ but } (\forall B)[F_n^A \not\leq_{(k-1)\text{-T}} B]].$$

Proof. (i) Follows from Theorem 6.1 and the definitions.

(ii) Follows from Theorem 6.1 and the definitions.

(iii) Follows from the proof of Theorem 6.1 and Theorem 2.4(i). □

Since some other separation results in complexity theory hold with bi-immunity [3, 14, 15], we might wonder if Corollary 6.2(i) holds with bi-immunity. In other words, does there exists a k-cheatable set A such that neither A nor $\bar{A}$ contains a $(k-1)$-cheatable subset? To the contrary, we show that A or $\bar{A}$ must contain a 1-cheatable subset.

Theorem 6.3. *If A is k-cheatable then A or $\bar{A}$ contains an infinite 1-cheatable subset.*

Proof. By the Nonspeedup Theorem [8], all k-cheatable sets are recursive. By Lemma 5.1(iii), if A is recursive then A or $\bar{A}$ contains an infinite 1-cheatable subset. □

Corollary 6.4. *If A is k-cheatable (where $k \geq 1$) then A or $\bar{A}$ contains an infinite $(k-1)$-cheatable subset.*

Proof. The result for $k \geq 2$ is established in Theorem 6.3. The result for $k = 1$ follows because no 1-cheatable set is bi-immune for P. □

Acknowledgment

The author expresses his warmest appreciation to his thesis advisor, John Gill, who supervised some of this work. The author wishes to thank Judy Goldsmith for helpful discussions of bi-immune sets; Alan Selman for helpful discussions of self-reducible sets; Bill Gasarch and Amir Amihood for pointing out that our original proof of Lemma 4.3 generalized to arbitrarily large time bounds, and also for suggesting that we simplify the proof by establishing it first for sets over the alphabet {0}; and Cathy Schevon and Dwight Wilson for reading early drafts of this paper. The author also wishes to thank the referees for suggesting that the introduction review the contrasts between cheatability and non-p-superterseness, and the relationships between cheatability and other notions in complexity theory. Finally, the author wishes to thank the editor, Ron Book, for suggesting the use of more standard notation.
